

Okay, the question is: What is the best way to measure the performance? That is, what should I compare the performance against? What is the x-value?

I originally started with the path length. Which is stupid, because a short path can take a long time to find. Then, I went over to total weight. Which was slightly better but still not perfect, because of differences in “density”. Then I took the count of expanded nodes, which is also not perfect because the same node can be visited multiple times during execution. So now, I’m at the total count of all visited nodes, counting the same node multiple times if it has been visited multiple times.

This is easy to measure in classic, but using-key overwrites old values, so I cannot simply count the number of entries in the Union Table. Maybe I have to carry a counter. But would this impact performance? It shouldn’t, but maybe it does.
