

Consider two alternative version of classic lcs.

1. “normal” version

```
WITH current_row(y) AS (  
    SELECT max(yidx) + 1  
    FROM lcs  
    WHERE xidx = length(s1())  
)  
FROM lcs  
WHERE  
    -- when the current row number is larger than the maximal row number, terminate  
    (SELECT y FROM current_row) <= (SELECT y FROM max_row)
```

2. modified version

```
WITH current_row(y) AS (  
    SELECT max(yidx) + 1  
    FROM lcs  
    WHERE xidx = length(s1())  
)  
SELECT  
    lcs.*  
FROM  
    lcs JOIN -- manually carry table  
    current_row ON lcs.yidx >= current_row.y - 1 JOIN -- choose only relevant rows  
    max_row ON current_row.y <= max_row.y -- termination condition
```

The code snippets show the start of the query’s iterative part. With the modified version, my goal was to achieve better performance by selecting only the data that we need to proceed, in contrast to the entire table in the first query. However, upon testing, the second query quickly proved itself to be way inferior. The many JOIN-operations appear to be too costly.
